Table S1. d-band center values (ε_d, in eV) for the 44 surface (Ru$_s$) and 11 core (Ru$_c$) Ruthenium atoms in various compounds; q = average Mulliken atomic charges per atom (in |e|, Ru$_s$ atoms, all Ru atoms, NH$_x$* and H*).

It is noteworthy that the overall charge is positive for NH$_3$ and negative for NH$_2$, whereas the metal surface is almost neutral when stabilized by NH$_3$ only and oxidized when stabilized by NH$_2$. The surface is of course even more oxidized when hydrides are also present at the surface. The H and NH$_2$ co-adsorption also significantly stabilizes the surface d-band center.

**Table S2.** DFT energies and total electron magnetic moments (μ) of the Ru$_{55}$ NPs model systems and adsorbates considered in this work.

Figure S6. Density of states (DOS), selection of DOS projected on AOs (pDOS) and COHP profiles for $Ru_{55}(NH_3)_{22}$, $Ru_{55}(NH_2)_{22}$ and $Ru_{55}H_{43}(NH_2)_{22}$. The d-band center value, $\varepsilon_d(Ru_s)$, and the center of mass of the N* pDOS, $\varepsilon(N^*)$, are given relatively to the Fermi energy. A Lewis-like localized bonding scheme is also shown both for Ru-NH$_3$ and Ru$_2$-NH$_2$ fragments.

Let us first examine the DOS profile for $Ru_{55}(NH_2)_{22}$. First, no doubt about the metallic character of this nanocluster (blue profile). The d-projected DOS for surface Ru atoms, pDOS(d_{Ru_s}), relative to the Fermi energy, is in line with 7.2e/Ru occupation of this d band. $\varepsilon_d(Ru_s)$ lies 2.65 eV below the Fermi energy. It is very close to the value calculated for the bare Ru_{55} nanocluster, 2.57 eV (see also Table SIDFT1). This weak stabilization w.r.t. to Ru_{55} is in agreement with the weak σ-donor character of the NH$_3$ ligand. As already observed in previous

studies,[1] the pCOHP profile shows that the metal electronic states just below the Fermi energy are anti-bonding. The most stable metal states then acquire a metal-metal bonding character, and the overall cohesion of the metal surface is related to the excess of metal bonding states with respect to anti-bonding states. The simultaneous examination of the DOS and pCOHP profiles shows that the electronic states around -7 eV have components both on Ru and NH_3, resulting in a bonding Ru-N interaction (pCOHP profile, red curve). The bonding pattern is different for NH_2, with both a σ-donation and a covalent bonding. It can be seen both from the pDOS and pCOHP profiles and from electron charges reported in Table SIDFT1.
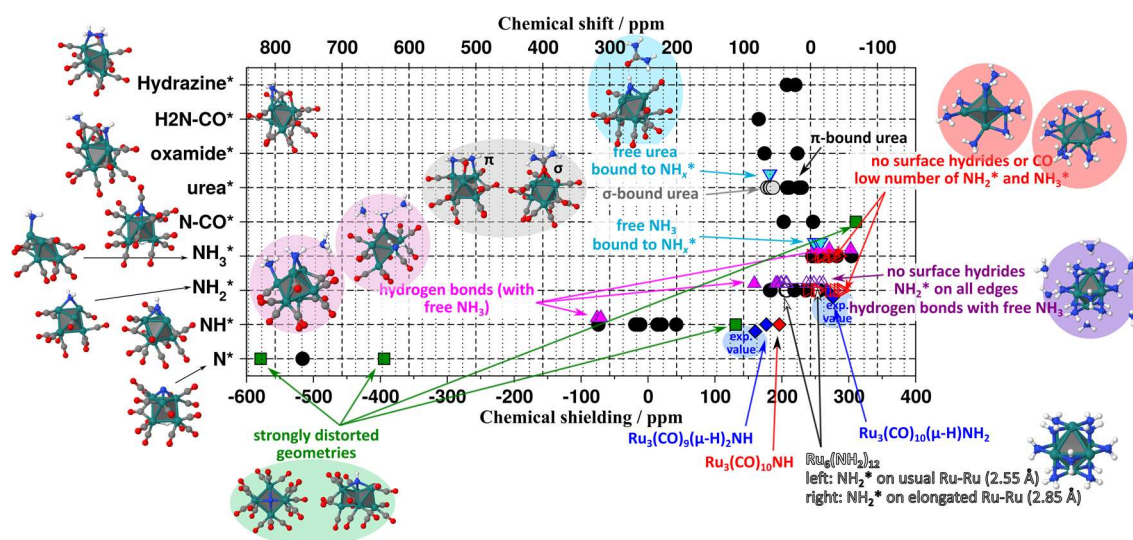

Figure S7. ^{15}N NMR chemical shieldings calculated in 46 [Ru$_6$] clusters at the DFT-PBE0 level of theory (* stands for "adsorbed"). Some geometries are also shown.

The chemical shielding is calculated by considering the simulated value of liquid ammonia at the same level of calculation: $\delta = \sigma$(theoretical value for N in liquid ammonia) $- \sigma$(N of the sample); see computational details. These calculated chemical shieldings were used to define the resonance domains of Figure 5 of the article.

- Results are also given for nido [Ru$_3$] clusters with 48 (=14n+6) valence electrons ($\blacklozenge$) and compared to experiments. [2] The agreement is very good.
- **η-NH$_3$** (on-top NH$_3$) systematically resonate at $\delta < 0$, independent of the models, i.e. adsorbed on the [Ru$_6$(CO)$_n$] models ($\bullet$), or making hydrogen bonds from the second sphere of coordination with surface species ($\blacktriangledown$), or adsorbed on undercoordinated [Ru$_6$(NH$_x$)$_n$] models ($\triangleright$). Adsorbed NH$_3$ ligands are not significantly unshielded by hydrogen bonds with ammonia molecules in the gas phase ($\blacktriangle$).
- The situation with **μ-NH$_2$** (edge-bridging NH$_2$) is more contrasted, i.e. the chemical shift is usually observed in the ~0 to 60 ppm domain ($\bullet$), and again hydrogen bonds do not significantly unshield the NMR signal ($\blacktriangle$). Negative chemical shifts are also found: δ(N) is observed both experimentally and theoretically at ~ -33 ppm for the very small Ru$_3$(CO)$_{10}$(μ-H)NH$_2$ cluster ($\blacklozenge$); a strong shielding (δ ~ -11 ppm) is also calculated for NH$_2$ ligands adsorbed on significantly long Ru-Ru bonds on the Ru$_6$(NH$_2$)$_{12}$ cluster ($\bigcirc$); it is even more strongly shielded for undercoordinated [Ru$_6$(NH$_x$)$_n$] models ($\triangleright$), with δ ~ -20 to -40 ppm.
- In very small [Ru$_3$] clusters the ^{15}N NMR chemical shift of **μ$_3$-NH** (face-capping NH) is observed at ~ 50 – 80 ppm ($\bullet$). When adsorbed on an atypical coordination site of one [Ru$_6$(CO)$_n$] model ($\blacksquare$), N is found to resonate at ~ 105 ppm. Apart from these singular cases, μ$_3$-NH is expected to be observed in the ~ 200 to 300 pm domain.
- **μ$_3$-N** is strongly downfield shifted at ~ 750 ppm ($\bullet$).

- NH$_2$ in σ-bound **urea** (see 3D representation on the Figure S8, urea is bound to the surface by the oxygen lone pairs) is found to resonate at the same value as free urea (●), *i.e.* ~ 60 ppm, whereas the π coordination involves a significant shielding by ~ 20 to 40 ppm (●). It turns out that π-coordinated urea could be observed in the same domain as μ-NH$_2$*, in line with the pyramidalization of the nitrogen atoms.
- **Hydrazine** has been considered as well. The simultaneous σ coordination of the two nitrogen lone pairs brings δ close to 30 ppm (●), similarly to π-coordinated urea and to "standard" edge-bridging (or μ) NH$_2$*.

Computational details.

DFT calculations of metal nanoclusters. Software: Vienna ab initio simulation package, VASP [3, 4]; spin polarized DFT; exchange-correlation potential approximated by the generalized gradient approach proposed by Perdew, Burke, and Ernzerhof (PBE) [5]; projector augmented waves (PAW) full-potential reconstruction [6, 7]; PAW data sets for Ru treating the $(n-1)p$, $(n-1)d$ and ns states (*i.e.* 14 valence electrons); kinetic energy cutoff: 500 eV; Γ-centered calculations [8]; Gaussian smearing (σ) of 0.02 eV width, energies being therefore extrapolated for $\sigma = 0.00$ eV; geometry optimization threshold: residual forces on any direction less than 0.02 eV/Å; supercell size: $20\times23\times20$ Å^3 (ensures a vacuum space of *ca.* 10 Å between periodic images of the nanoclusters).

Ru$_{55}$ model. The model is a hcp spheroid. Its geometrical characteristics, as well as a H-coverage study were previously published in ref.[9]. It has also been used to study the adsorption properties of phenylpyridine [10] and of ethanoic acid [11] at the surface of hydrogenated RuNPs.

Adsorption energies.

$$E_{\mathrm{ads}}(\mathrm{H}) = \frac{1}{n}\left[E\left(n\mathrm{H}^*\right) - E(\mathrm{NP}) - \frac{n}{2}E(\mathrm{H}_2)\right]$$

$$E_{\mathrm{ads}}(\mathrm{L}) = \frac{1}{n}\left[E\left(n\mathrm{L}^*\right) - E(\mathrm{NP}) - nE(\mathrm{L})\right]$$

i.e. in the case of hydrides it is a dissociative adsorption energy.

COHP and DOS profiles. The LOBSTER package [12] which has been used in this work allows the calculation of Crystal Orbital Hamilton Population (COHP) curves projected onto an atomic Slater basis set (pCOHP), and also reliable atom-projected density of states (pDOS), both directly based on plane-wave wave-function calculated with the VASP package. The projection of the PAW wavefunction was achieved using the pbeVASPfit basis set. COHP is a partitioning of the band-structure energy in terms of orbital-pair contributions[13]. Some examples of its application to RuNPs can be found in Refs. [1, 9] and [10]

Charge calculations. A Mulliken population analysis (MPA) from VASP wavefunction was performed by integrating up to the Fermi energy with LOBSTER. The charge spilling, a criterion that assesses the quality of the projection, was systematically lower than 1.0%. A comparison of such MPA charges with other electronic density decomposition schemes (AIM-Bader, Natural Population Analyzis, CM5) can for example be found in ref. [14]

d-band center values (ε_d). They were calculated from the pDOS obtained with LOBSTER, see details in Ref.[1] The principle underlying this d-band center model[15] is that the binding energy of an adsorbate to a metal surface is largely dependent on the electronic structure of the surface itself. The closer ε_d to the Fermi energy (E_F), the stronger the bonding on the surface. A large ($E_F - \varepsilon_d$) involves weak adsorption energies.

NMR calculations. All DFT calculations on the [Ru$_3$] and [Ru$_6$] clusters were performed with Gaussian09.[16] Calculations were carried out at the DFT level of theory using the hybrid functional PBE0.[17] Geometry optimizations were achieved without any symmetry restriction. Calculations of vibrational frequencies were systematically done in order to characterize the nature of stationary points. Stuttgart effective core potential[18] and their associated basis set was used for Ruthenium, augmented by a set of polarization functions ($\zeta_f = 1.235$). For the other elements (H, C, O, and P), Pople's polarized double-ζ basis set 6-31G(d,p)[19, 20] was used. The optimized structures were used for ^{15}N NMR calculations. Among the various theories available to compute chemical shielding tensors, the gauge including atomic orbital (GIAO) method was adopted for the numerous advantages it presents.[21-26] Calculating a theoretical chemical shift requires the knowledge of the chemical shielding of a reference, since it is explicitly calculated as $\delta = (\sigma_{ref} - \sigma)$, in ppm. We have shown in previous studies on ruthenium clusters that DFT-GIAO provides ^{1}H, ^{13}C in good agreement with experimental data and analysis.[27-30] The experimental reference chemical shift for ^{15}N corresponds to ammonia in its liquid phase. The theoretical ^{15}N chemical shift has been calculated using the same strategy as in Ref.[31], with $\sigma_{iso(ref)} = 242.8$ ppm.[32] A previous study done on betaine adducts-protected RuNPs showed a good agreement between theoretical and experimental ^{15}N NMR chemical shifts. [31]

Ab initio thermodynamics. Let us consider a co-adsorption process of two species, L_1 and L_2, which is the starting point of the Langmuir–Hinshelwood mechanism in heterogeneous catalysis. It can be summarized as: MNP + n_1L_1 + n_2L_2 → n_1L_1* + n_2L_2*, (MNP = metal nanoparticle and * stands for "chemisorbed") and the Gibbs free energy for this reaction is calculated as:

$$\Delta G_{ads}(T, L_1, L_2) = [\Delta G° - n_1\mu(L_1) - n_2\mu(L_2)]/A$$

Where A is the surface area of the MNP, μ are chemical potentials and $\Delta G°$ is calculated after DFT energies and vibrational contributions to energies.

The free energy diagram of Figure 4 was calculated with our in-house *aithermo* software. Methodological details and examples of applications can be found in Refs. [1, 9, 11]. Yet, *aitermo* is made to study adsorption processes only, whereas for example accounting for $Ru_{55}(NH_2)_{22}$ would require to consider the reaction $Ru_{55}(NH_3)_{22}$ → $Ru_{55}(NH_2)_{22}$ + $11H_2$. This is why the stability diagram of Figure 4 is based on the calculation of $\Delta G_{ads}(T,p_{H2})$ for the following isomers only: $Ru_{55}(NH_3)_{22}$, $Ru_{55}H_{22}(NH_3)_{22}$, $Ru_{55}H_{44}(NH_3)_{22}$, $Ru_{55}H_{70}(NH_3)_{22}$, $Ru_{55}H_{33}(NH_3)_{11}(NH_2)_{11}$ and $Ru_{55}H_{55}(NH_3)_{11}(NH_2)_{11}$. It also explains the abrupt transition between the yellow and blue domains in Figure 4, that does not account for the preliminary conversion of NH_3 into NH_2. Such conversion is qualitatively introduced, given the NH_3 → NH_2 thermodynamic driving force calculated for low H coverage. The Ru-H vibrational contribution is accounted for, whereas Ru-N is neglected. The Ru-H vibrational contribution is accounted for, whereas Ru-N is neglected. The resulting stability diagram gives the most stable surface composition of the samples in equilibrium under a given pressure p_{H2} and temperature T. Mind that without other chemisorbed ligands, 1.6 $H/Ru_{surface}$ was found to be the equilibrium composition under standard temperature and pressure conditions. It turned out to be in agreement with experimental quantitative analysis done on RuNPs stabilized with PVP. [9] Such model incorporates an elongated, undissociated H_2 on an apex, in line with the weaker back donation from the metal to the σ*(H_2) MO for such highly saturated RuNPs. On lowering surface coverage, dihydrogen molecules dissociate on the surface.
