Experimental Section

Preparation of tungsten carbide/carbon nanocomposites

Firstly, 1.0 g of dicyandiamine (DCA) and a required amount of ammonium metatungstate (AMT) were thoroughly ground in an agate motar for 20 mins. The resultant solid mixture was then pyrolyzed at 400 $^{\circ}$C for 0.5 h, then kept at 800 $^{\circ}$C for 5 h under N_2 atmosphere, and the flow rate of N_2 was controlled at 2.5 mL/min. The heating rates from room temperature to 400 $^{\circ}$C and from 400 $^{\circ}$C to 800 $^{\circ}$C were 2 $^{\circ}$C/min and 5 $^{\circ}$C/min, respectivley. The products were denoted as WC/C-*n* in sequence with the weight ratio of AMT to DCA ranging from 0.3 to 5.0. WC/C-1, WC/C-2, WC/C-3 and WC/C-4 correspond to 1:0.3, 1:1, 1:3 and 1:5 of the weight ratio of AMT to DCA, respectively.

Preparation of Janus film with carbide/carbon nanocomposites and cotton cloth

In a typical recipe, 50 mg of WC/C-*n* was dispersed in 0.5 mL of DMF by ultrasonication for 1 hour and stirring for 1 hour to make an aqueous dispersion. Then 15 mg of PVDF was added to the solution and stirred vigorously at room temperature overnight. Finally, a cotton cloth with the area of about 7 cm^2 was spread on a heating plate with 70 $^{\circ}$C, and then the mixed solution was evenly brushed with a brush on the surface of cotton cloth. The resultant Janus film was further denoted as JF-*n*, where *n* referred to the sample of WC/C-*n* in corresponding film.

Characterization

X-ray diffraction (XRD) data were obtained by a Rigaku D/MAXRC X-ray diffractometer (45.0 kV, 50.0 mA) using Cu Kα source. X-ray photoelectron spectroscopy (XPS, Kratos, ULTRA AXIS DLD) was recorded to study the surface states with monochrome Al Kα (hv=1486.6 eV) radiation. Transmission electron microscopy (TEM) images were obtained on a Tecnai F20 instrument operating at an

accelerating voltage of 200 kV. The thermogravimetric analysis was carried out on a SDT Q600 thermogravimetric analyzer (TGA) in the temperature range of room temperature to 800 °C at a heating rate of 10 °C/min under air atmosphere. UV-vis diffuse reflectance spectra were achieved useing a UV-vis spectrophotometer (Lambda 950 (PerkinElmer, USA)) in the range of 200-2500 nm. Metal concentration was made with an Optima 8300 (PerkinElmer, USA) ICP-OES. Total organic carbon (TOC) was determined by Analytik Jena AG MultiN/C 2100 TOC analyzer. The water contact angle was measured by a Goniometer instrument equipped (JC 2000C, ZhongChen, China). A thermal infrared imager (Fotric 225s, China) was used to measure the temperature changes and distributions under light illumination.

Solar-driven water evaporation experiments

The solar-driven water evaporation rate and the solar thermal conversion efficiency were evaluated by the following experiments. All solar-driven water evaporation experiments were conducted by using a solar simulator (CEL-PE300L) with an AM 1.5 filter. A homemade vessel with a surface area of 7.1 cm^2 was used as the evaporation device. A certain amount of 3.5 wt% NaCl solution was added into the vessel. Then, JF-n was added into the vessel on the saline water surface. Afterwards, the whole vessel was placed on an analytical electronic balance connected with a computer and illuminated by a light source as mentioned above. An infrared camera was used to measure the surface temperature of JF-n. For the cyclic evaporation tests, the test time of each cycle was 1 h, JF-3 was washed with water and vacuum dried after each test, and then used for the next cycle of evaporation. The solar energy efficiency (η) for the solar water evaporation can be calculated according to the following equation:

$$\eta = mh_{LV}/C_{opt}P_0 \tag{1}$$

where m is the steady-state water evaporation rate (kg m^{-2} h^{-1}), h_{LV} is the latent enthalpy of vaporization (kJ kg^{-1}) of the liquid-vapor phase change, C_{opt} is the optical

concentration and P_0 is the solar optical power of one sun (1 kW m^{-2}). The value of h_{LV} varies with temperature. In our experiments, due to the narrow temperature range and the evaporation through large inter-particle voids, the value of h_{LV} only varies very slightly with temperature and thus a constant value of 2260 kJ kg^{-1} is adopted for the calculation.

First-Principles Calculation

DFT calculation was carried out with General Gradient Approximate (GGA) method using Perdew-Burke-Ernzerhof (PBE) exchange-correlation function for geometry optimizations and self-consistent total energy calculation. Calculation was performed with Cambridge Sequential Total Energy Package (CASTEP); the cut-off voltage of plane wave is set at 700 eV, and the total energy convergence at 10^{-6} eV for the self-consistent iterations. Gaussian smearing method with σ=0.05 eV was considered for Brillouin-zone integrations on a 1×1×1 k-mesh. The geometry optimization was performed using a damped molecular dynamics scheme until the forces on the atoms were <0.01 eV/Å. To calculate the phonon spectrum and energy band, the direction of energy was manually selected in Brillouin zone. The setting method was that when calculating the band structure, one should select K points firstly, and different K points corresponded to different convergence accuracy.

Finite Difference Time Domain Simulation (FDTD simulation)

Finite Difference Time Domain Method (implemented on Lumerical ''FDTD Solutions'' software package) was utilized for modeling of tungsten carbide nanoparticles (Fig. S12). The diameters of nanoparticles were normalized to the size which was close to that from TEM images. TE polarized plane wave was defined over three-dimensional nanoparticles. For plane wave simulation, a periodic boundary condition was applied in the x and y axial direction, and domains to the side of the clusters were surrounded by water and perfectly matched layers (PMLs). Parameters of tungsten carbide were as follows: the type was Debye-Drude, conductivity was

126,000 S m^{-1}，infinite Freq. relativepermittivity was 5.5, static relative permittivity was 5.5, and density was 17.121 g cm^{-3} from standard PDF card.

WC/C-1 and WC/C-2 are stable before 400 °C and display obvious weight increases in the temperature of 400-700 °C. The weight increase should be attributed to the oxidation of WC particles at high temperature. Although carbon combustion is a weight-loss step, these two samples still gain a certain of weight after TG measurements, indicating that their contents of carbon nanosheets are relatively low. In contrast, WC/C-3 and WC/C-4 show similar weight increases in the temperature range of 300-500 °C, while their total weights drastically decrease after the test. WC/C-3 and WC/C-4 have smaller WC nanoparticles, and thus their onsets for weight increase shift to lower temperature. Meanwhile, their high contents of carbon nanosheets can offset the oxidation of WC nanoparticles. Considering that the final oxidation product of WC nanoparticles is WO_3, one can estimate the specific content of carbon nanosheets with equation:

$$R\,wt\% = (1 - C\,wt\%)\frac{M_{WO_3}}{M_{WC}}$$

(2)

where R wt%, C wt%, M_{WO3}, and M_{WC} are referred to remaining weight percentage, carbon nanosheets content, WO_3 formula weight, and WC formula weight, respectively. The calculation results suggest that the specific contents of carbon in WC/C-1, WC/C-2, WC/C-3, and WC/C-4 are 1.9%, 7.2%, 26.5%, and 32.1%, respectively.
