#### **Reagents and Instruments:**

Nickel chloride ( $\text{NiCl}_2$ ) and Vanadium chloride ( $\text{VCl}_3$ ) were sourced from Sigma-Aldrich. Benzene tricarboxylic acid (BTC) was purchased from Sigma-Aldrich. All electrochemical characterizations were conducted using a Metrohm Autolab. The Hg/HgO as reference and Pt as counter (in 1 M KOH) were purchased from CH Instruments. A carbon cloth (CC) from Alfa-Aesar served as the working electrode. Throughout the experiments, DI water was used. The catalysts, prepared in various stoichiometric ratios, underwent characterization using HR-TEM (Tecnai<sup>TM</sup> G2 TF20 at 200 kV) and Talos F-200-S with HAADF elemental mapping. Colour mapping and EDS analysis were performed using the FESEM instrument (SUPRA 55VP Carl Zeiss) equipped with an EDS detector. The XRD scans were done at a rate of  $5^\circ \text{ min}^{-1}$  within the  $2\theta$  range of  $10\text{-}80^\circ$  on a Rigaku X-ray diffractometer, using  $\text{Cu K}\alpha$  radiation. Lastly, XPS evaluations were executed on a Theta Probe AR-XPS system by Thermo Fisher Scientific, UK.

### **Electrochemical Characterizations:**

Electrocatalytic investigations were performed using a conventional three-electrode setup. For the Oxygen Evolution Reaction (OER) experiments, Carbon cloth (CC) was employed as the counter electrode. The reference electrode chosen for OER was Hg/HgO. Polarization assessments were conducted at a deliberately slow scan rate of 5 mV/sec. A manual 85% iR compensation was applied, utilizing  $R_s$  data obtained from Electrochemical Impedance Spectroscopy (EIS). To assess accelerated degradation (AD), continuous rapid sweeps were conducted through 1000 cycles at a significantly high sweep rate of  $150 \text{ mV s}^{-1}$ , all within a 1 M KOH solution. Electrochemical impedance studies encompassed a frequency spectrum from 1 Hz to 100 kHz.

### Electrode fabrication:

The electrodes were fabricated using the traditional drop-casting technique onto carbon cloth (CC) substrates. A catalytic ink was formulated by mixing water, ethanol, and nafion in a ratio of (7.5:2:0.5) to produce a 1 mL solution. Subsequently, 34.5  $\mu\text{L}$  of the resulting solution was drop-casted onto the CC and then dried at a temperature of 60°C. The dried electrode thus prepared was employed as the working electrode (with a catalyst loading of 0.1  $\text{mg}/\text{cm}^2$ ) for the OER process.

### $C_{dl}$ Calculation:

The double layer capacitance ( $C_{dl}$ ) was determined from a CV in the range of 0.2 to 0.3 V vs Hg/HgO electrode at a scan rate of 30, 60, 90, 120, and 150 mV/s, using the equation:  $C_{dl} = \Delta j / (j_a - j_c) / 2v$ , where  $j_a$  and  $j_c$  are anodic and cathodic current densities and  $v$  is the scan rate in  $\text{mVs}^{-1}$ .<sup>1</sup> The non-Faradic current density-based electrochemically active surface area (ECSA) was estimated according to the equation:  $\text{ECSA} = C_{dl} / C_s$ , where  $C_s$  is the specific capacitance of the electrode in 1 M KOH electrolyte. Finally, we calculate  $C_{dl}$  using the slope of the graph  $\Delta j$  vs  $v$ .

### ❖ Determination of Surface concentration of various alloys from the redox features of CV:

- Calculated area associated with the reduction of  $\text{Ni}^{3+}$  to  $\text{Ni}^{2+}$  of **Ni-BTC** = 0.000494 VA

Hence, the associated charge is =  $0.000494 \text{VA} / 0.005 \text{Vs}^{-1}$

$$= 0.0988 \text{As}$$

$$= \mathbf{0.0988 \text{ C}}$$

Now, the number of electron transferred is =  $0.0988 \text{ C} / 1.602 \times 10^{-19}$

$$= \mathbf{6.16729 \times 10^{17}}$$

Given that the reduction of Ni<sup>3+</sup> to Ni<sup>2+</sup> involves a single electron transfer reaction, the quantity of electrons computed previously corresponds precisely to the count of active sites at the surface.

Hence, the number of Ni participating in OER is = **6.16729×10<sup>17</sup>**

In our study, the determination of Turnover Frequency (TOF) from OER Current Density TOF was calculated assuming that the surface-active Co atoms that had undergone the redox reaction just before onset of OER only participated in OER electrocatalysis. The corresponding expression is,

$$\text{TOF} = (j \times N_A) / (F \times n \times \Gamma)$$

Where, j = current density N<sub>A</sub> = Avogadro number F = Faraday constant n = Number of electrons Γ = Surface concentration.

Hence, we have,

$$\begin{aligned} \text{TOF}_{1.60\text{ V}} &= [(0.00985) (6.023 \times 10^{23})] / [(96485) (4) (6.16729 \times 10^{17})] \\ &= \mathbf{0.024920845 \text{ sec}^{-1}} \\ &= \mathbf{89.71504041 \text{ h}^{-1}} \end{aligned}$$

- Calculated area associated with the oxidation of Ni<sup>3+</sup> to Ni<sup>2+</sup> of NiV-BTC = 0.00006 VA

Hence, the associated charge is = 0.00006 VA / 0.005 Vs<sup>-1</sup>

$$\begin{aligned} &= 0.012 \text{ As} \\ &= \mathbf{0.012 \text{ C}} \end{aligned}$$

Now, the number of electron transferred is = 0.012/ 1.602 ×10<sup>-19</sup>

$$= \mathbf{7.49064 \times 10^{16}}$$

Given that the reduction of Ni<sup>3+</sup> to Ni<sup>2+</sup> involves a single electron transfer reaction, the quantity of electrons computed previously corresponds precisely to the count of active sites at the surface.

Hence, the number of Ni participating in OER is = **7.49064×10<sup>16</sup>**

Hence, we have,

$$\begin{aligned}
\text{TOF}_{1.60\text{ V}} &= [(0.0238) (6.023 \times 10^{23})] / [(96485) (4) (7.49064 \times 10^{16})] \\
&= \mathbf{0.495768788 \text{ sec}^{-1}} \\
&= \mathbf{1784.767636 \text{ h}^{-1}}
\end{aligned}$$

### Activation energy calculation:

The temperature-dependent kinetic analysis was employed to assess the influence of V on the apparent activation energy ( $E_{\text{app}}$ ) and pre-exponential factor ( $A_{\text{app}}$ ) of NiV-BTC electrocatalysts. This analysis aimed to gain insights into how V affects the catalytic mechanism. Cyclic voltammetry (CV) curves were obtained for both Ni-BTC and NiV-BTC samples in a 1.0 M KOH solution over a temperature range of 25 to 50°C. As expected, the oxygen evolution reaction (OER) activities of both samples increased with rising temperature. The values of both catalysts at constant overpotentials were determined using the Arrhenius equation. This equation can be expressed as follows:

$$j = A_{\text{app}} \exp (E_{\text{app}}/RT)$$

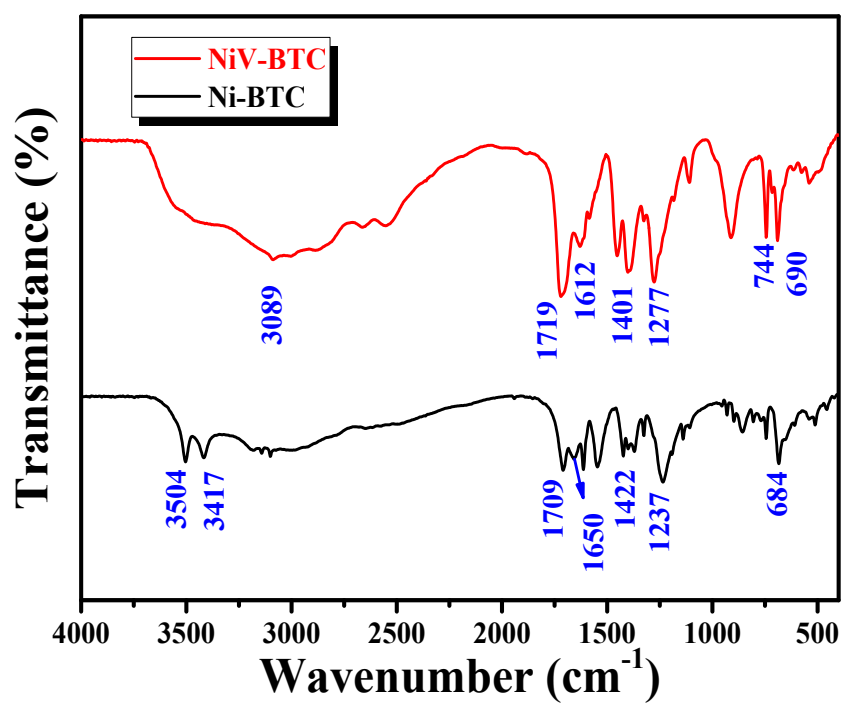

Where:

$j$  is the current density normalized by ECSA,  $k$  is the rate constant for the reaction,  $A$  is the pre-exponential factor ( $A_{\text{app}}$  in this case),  $E_{\text{app}}$  is the apparent activation energy,  $R$  is the universal gas constant (8.314 J/(mol·K)),  $T$  is the absolute temperature in Kelvin.

Thus, the  $E_{\text{app}}$  values at different potentials can be calculated by fitting the slope of the Arrhenius curve by using the following equation:

$$\delta \ln(j) / \delta (1/T) = - E_{\text{app}}/R$$

So, the slope of this equation is: Slope =  $E_{\text{app}}/R$ , and the intercept of  $\ln(j)$  against  $1/T$  curve is the  $\ln (A_{\text{app}})$ .
