## 1. Experimental Details

### 1.1 Crossed Molecular Beam Experiments

### 1.1.1 Beam conditions

The study of the title reaction has been possible following the development in our laboratory of a continuous supersonic beam of nitrogen atoms containing, in addition to the electronic ground state ${ }^{4} \mathrm{~S}$, a sizeable amount of the excited, metastable state ${ }^{2} \mathrm{D}$. This has been achieved via a high-pressure radiofrequency (RF) discharge beam source described in Ref. 1. The atomic nitrogen beam used in this experiment was produced by discharging 90 mbar of a $2.5 \% \mathrm{~N}_{2} / \mathrm{He}$ gas mixture through a water-cooled 0.48 mm diameter quartz nozzle at 250 W of RF power. The beam was collimated by a 0.8 mm diameter boron nitride skimmer and a further defining aperture to an angular divergence of $2.4^{\circ}$. High molecular dissociation (about 60\%) was achieved. Atomic nitrogen was produced in a distribution of electronic states which has been characterized in our laboratory by Stern-Gerlach magnetic analysis: $72 \%$ of N atoms are in the ${ }^{4} \mathrm{~S}$ ground state, while $21 \%$ and $7 \%$ are in the metastable excited states ${ }^{2} \mathrm{D}$ and ${ }^{2} \mathrm{P}$ states, respectively. ${ }^{1}$ The resulting beam peak velocity and speed ratio were $2253 \mathrm{~m} / \mathrm{s}$ and 4.6 , respectively. In our previous experiments on $\mathrm{N}\left({ }^{2} \mathrm{D}\right)$ reactions, ${ }^{2-16}$ we verified that the presence of $\mathrm{N}\left({ }^{4} \mathrm{~S}\right)$ and $N\left({ }^{2} \mathrm{P}\right)$ in the nitrogen beam did not affect the experimental outcomes as there are no features in the scattering distributions that can be associated to their reactions. Indeed, the rate constants of $N\left({ }^{4} S\right)$ and $\mathrm{N}\left({ }^{2} \mathrm{P}\right)$ reactions with several hydrocarbons are known to be much smaller with respect to those of $\mathrm{N}\left({ }^{2} \mathrm{D}\right)$ and/or non-reactive. ${ }^{17-19}$ This seems to be the same also for the title reaction as no clue of more energetic products from the $\mathrm{N}\left({ }^{2} \mathrm{P}\right)$ reactions are present in the scattering distributions. Notably, a recent experiment on the reaction of $N\left({ }^{2} \mathrm{P}\right)$ with toluene ions suggests that at least the reactions with charged species can be efficient for the ${ }^{2} \mathrm{P}$ state of atomic nitrogen. ${ }^{20}$

The supersonic beam of benzene was generated by expanding 103 mbar of neat gas ( $99.8 \%$ purity) through a 0.1 mm diameter stainless-steel nozzle, followed by a 0.8 mm skimmer and a further defining aperture (beam angular divergence $3.8^{\circ}$ ). The benzene pressure was kept constant by maintaining a sample of liquid benzene at $17^{\circ} \mathrm{C}$ (the Pyrex flask containing liquid benzene was immersed in a water/ethylene glycol bath). The peak velocity of benzene was measured to be $521 \mathrm{~m} / \mathrm{s}$ with a speed ratio of 4.2.

### 1.1.2 Time-of-flight spectrum at $m / z=91$ and $m / z=65$ recorded at $\Theta=48^{\circ}$

The presence of two different contributions to the signal recorded at $\mathrm{m} / \mathrm{z}=65$ is clearly visible also in the TOF spectra. Fig. S1 compares the TOF spectra at $m / z=91$ (top panel) and $m / z=65$ (bottom panel) at $\Theta=48^{\circ}$ and relates them to the Newton diagram (note that the Newton diagram is represented in the velocity space while the TOF distributions are recorded in the time space). As can be seen, the TOF spectrum recorded at $m / z=91\left(\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{~N}^{+}\right)$at the LAB angle $\Theta=48^{\circ}$ (close to the CM angle) is characterized by a slow peak centered at about $380 \mu \mathrm{~s}$, which corresponds to nearly the velocity of the center-of-mass of the system and is attributed to the heavy co-product(s) of gross formula $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{~N}$ in the H -displacement channels. The similar peak observed at $m / z=65$ is attributed to the same $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{~N}$ products detected at the -26 daughter ion $\mathrm{C}_{5} \mathrm{H}_{5}{ }^{+}$. A much faster peak at about $160 \mu \mathrm{~s}$ is also visible and this clearly corresponds to a completely different reaction product from another channel which, on the basis of energy and momentum conservation, can only be attributed to the cyclopentadienyl radical from the reaction channel (1) and/or (2) $\left(\mathrm{C}_{5} \mathrm{H}_{5}+\mathrm{HNC}\right.$ and/or $\left.\mathrm{C}_{5} \mathrm{H}_{5}+\mathrm{HNC}\right)$, with a possible contribution also from the channels (4) and (5). Unfortunately, on the basis of the product translational
energy distribution used to fit the LAB angular and TOF distributions at $m / z=65$ alone it is not possible to quantify the relative importance of the (1), (2), (4) and (5) channels.

Fig. S1 $m / z=91$ (top panel) and $m / z=65$ (bottom panel) TOF distribution recorded at $\Theta=48^{\circ}$. The black solid curves superimposed on the experimental data (dots) are the simulated TOF distributions obtained by using the best-fit CM functions shown in Fig. 4. In this case, the radius of each circle in the Newton diagram has been drawn considering the peak of the best-fit translational energy distributions).

### 1.2 Kinetic Experiments

### 1.2.1 $N\left({ }^{2} D\right)$ production

The photolytic production of $\mathrm{N}\left({ }^{2} \mathrm{D}\right)$ is not trivial, so these atoms were produced chemically during the present study, employing reaction (11) as a source as previously characterized by Nuñez-Reyes et $a l .{ }^{21}$

$$
\begin{align*}
& \mathrm{C}\left({ }^{3} \mathrm{P}\right)+\mathrm{NO} \rightarrow \mathrm{~N}\left({ }^{2} \mathrm{D},{ }^{4} \mathrm{~S}\right)+\mathrm{CO}  \tag{11}\\
& \mathrm{C}\left({ }^{3} \mathrm{P}\right)+\mathrm{NO} \rightarrow \mathrm{O}\left({ }^{3} \mathrm{P}\right)+\mathrm{CN} \tag{12}
\end{align*}
$$

The $\left.\left[\mathrm{N}\left({ }^{2} \mathrm{D}\right)+\mathrm{N}\left({ }^{4} \mathrm{~S}\right)\right] /\left[\mathrm{O}\left({ }^{3} \mathrm{P}\right)\right]\right)$ branching ratio has been estimated as $1.5 \pm 0.3$ at room temperature. ${ }^{22}$ $\mathrm{C}\left({ }^{3} \mathrm{P}\right)$ atoms were produced by the 266 nm pulsed laser photolysis of $\mathrm{CBr}_{4}$, introduced into the supersonic flow upstream of the Laval nozzle in trace quantities $\left(<4 \times 10^{13} \mathrm{~cm}^{-3}\right)$. For this purpose, solid $\mathrm{CBr}_{4}$ was held in a flask at a known pressure and temperature while a fraction of the carrier gas
flow was diverted through it ( $<70 \mathrm{sccm}$ ) before rejoining the main flow. Pulse energies lower than 40 mJ ( $10 \mathrm{~Hz}, 5 \mathrm{~mm}$ beam diameter) were employed here. Previous work has shown that excited state $\mathrm{C}\left({ }^{1} \mathrm{D}\right)$ atoms are also produced by $\mathrm{CBr}_{4}$ photolysis under similar conditions to the present experiments at the level of $10-15 \% .{ }^{23} \mathrm{C}\left({ }^{1} \mathrm{D}\right)$ atoms react rapidly with $\mathrm{NO},{ }^{24}$ and are expected to lead to the same products of (11) and (12). NO concentrations were kept at a constant value for each series of experiments at a specific temperature with values in the range (3.0-6.4) $\times 10^{14} \mathrm{~cm}^{-3}$. In contrast to $\mathrm{N}\left({ }^{2} \mathrm{D}\right)$ atoms, $\mathrm{C}\left({ }^{1} \mathrm{D}\right)$ atoms are rapidly quenched by collisions with $\mathrm{N}_{2},{ }^{25}$ whereas quenching with Ar is slow, ${ }^{26}$ so the influence of $\mathrm{C}\left({ }^{1} \mathrm{D}\right)$ reactions on $\mathrm{N}\left({ }^{2} \mathrm{D}\right)$ kinetics can be verified by performing experiments at the same temperature with both of these carrier gases. Such experiments were performed at room temperature during our recent studies of the $\mathrm{N}\left({ }^{2} \mathrm{D}\right)+$ allene reaction, ${ }^{13}$ with essentially identical rate constants obtained for both carrier gases.

### 1.2.2 $N\left({ }^{2} D\right)$ detection

The $\mathrm{N}\left({ }^{2} \mathrm{D}\right)$ atom kinetics were followed by pulsed laser induced fluorescence in the vacuum ultraviolet wavelength range (VUV LIF) at 116.745 nm via the $2 \mathrm{~s}^{2} 2 \mathrm{p}^{3} \mathrm{D}^{\circ}-2 \mathrm{~s}^{2} 2 \mathrm{p}^{3}\left({ }^{3} \mathrm{P}\right) 3 \mathrm{~d}^{2} \mathrm{~F}$ electronic transition. Tunable narrowband radiation at this wavelength was generated by first frequency doubling the output of a 10 Hz pulsed dye laser at 700.5 nm in a beta barium borate crystal. The residual dye laser radiation was separated from the UV beam at $350.2 \mathrm{~nm}(8-9 \mathrm{~mJ}$ per pulse) by two dichroic mirrors with peak reflectivity at 355 nm before being steered and focused into a frequency tripling cell attached to the reactor containing a mixture of Xe ( 40 Torr), with Ar added ( 560 Torr) for phase matching. The resulting tunable VUV beam was collimated by a $\mathrm{MgF}_{2}$ lens at the exit of the cell, which also served to steer it along a 75 cm long sidearm containing circular baffles and into the reactor where it crossed the supersonic flow at the level of the observation axis. This region was continuously flushed by $\mathrm{N}_{2}$ or Ar to minimize absorption of the VUV beam by reactive gases in the chamber. As the residual UV light was divergent after exiting the $\mathrm{MgF}_{2}$ lens, due to the difference in $\mathrm{MgF}_{2}$ refractive index between UV and VUV wavelengths, it was mostly blocked by the circular baffles. A fraction of the fluorescence emitted by unreacted $\mathrm{N}\left({ }^{2} \mathrm{D}\right)$ atoms within the reactor was collected at right angles to the flow and the probe laser beam by a lithium fluoride (LiF) lens which focused the VUV emission onto the photocathode of a solar blind photomultiplier tube (PMT). The sensitive envelope of the PMT and the LiF lens were protected from reactive gases within the chamber by a LiF window, while the zone between the LiF window and the PMT was evacuated by a dry pump to prevent further emission losses by atmospheric $\mathrm{O}_{2}$ absorption. The signal output of the PMT was processed by a boxcar integrator interfaced to a personal computer for display and averaging purposes. As the $\mathrm{CBr}_{4}$ molecules within the reactor scattered some of the photolysis laser light causing saturation of the PMT, all data recorded during the first five microseconds following the photolysis pulse were unexploitable. Approximately 100 time points were recorded to establish each kinetic profile, with time points consisting of the average signal of 30 individual laser shots. Fifteen of these time points occurred at negative time delays, that is, with the probe laser firing prior to the photolysis laser pulse to determine the baseline level.

### 1.2.3 Flow conditions and $\boldsymbol{C}_{6} \boldsymbol{H}_{6}$ concentration determination

Co-reagent $\mathrm{C}_{6} \mathrm{H}_{6}$ was carried into the reactor by bubbling a small fraction of the carrier gas flow $(<30 \mathrm{sccm})$ through a vessel containing $\mathrm{C}_{6} \mathrm{H}_{6}$ at room temperature and a known pressure. The $\mathrm{C}_{6} \mathrm{H}_{6}$
laden gas was flowed into a cold trap maintained at 290 K to ensure that the amount of $\mathrm{C}_{6} \mathrm{H}_{6}$ vapour exiting the trap corresponded to its saturated vapour pressure value at $290 \mathrm{~K} .{ }^{27}$ The exit of the cold trap was connected to the Laval nozzle reservoir via a heating hose maintained at 353 K . Upon entering the Laval nozzle reservoir, the $\mathrm{C}_{6} \mathrm{H}_{6}$ vapour was further diluted by the main carrier gas flow, so we assume that no further condensation losses occurred upstream of the cold trap. The carrier gas flows into the $\mathrm{CBr}_{4}$ vessel, the $\mathrm{C}_{6} \mathrm{H}_{6}$ flask and the main flow into the reactor as well as the NO flow into the reactor were all controlled by calibrated mass-flow controllers allowing the co-reagent NO and $\mathrm{C}_{6} \mathrm{H}_{6}$ concentrations to be calculated precisely. The gases themselves (Messer Ar 99.999\%, $\mathrm{N}_{2} 99.995 \%$, Linde Xe $99.999 \%$, Air Liquide NO 99.9\%) were flowed directly from the cylinders without further purification.

Fig. S2 $\mathrm{N}\left({ }^{2} \mathrm{D}\right.$ ) fluorescence signal, recorded at 127 K , plotted as a function of reaction time. (Solid blue squares) without $\mathrm{C}_{6} \mathrm{H}_{6}$; (solid green triangles) $\left[\mathrm{C}_{6} \mathrm{H}_{6}\right]=3.6 \times 10^{13} \mathrm{~cm}^{-3}$; (solid red circles) [ $\mathrm{C}_{6} \mathrm{H}_{6}$ ] $=1.7 \times 10^{14} \mathrm{~cm}^{-3} .[\mathrm{NO}]=4.6 \times 10^{14} \mathrm{~cm}^{-3}$ for all traces. Solid lines represent exponential fits to the data using expression (16).

Table S1 Second-order rate constants for the $\mathrm{N}\left({ }^{2} \mathrm{D}\right)+\mathrm{C}_{6} \mathrm{H}_{6}$ reaction alongside other relevant information.

| $\mathrm{T} / \mathrm{K}$ | $\mathrm{N}^{\mathrm{b}}$ | $\left[\mathrm{C}_{6} \mathrm{H}_{6}\right] / 10^{14} \mathrm{~cm}^{-3}$ | $[\mathrm{NO}] / 10^{14} \mathrm{~cm}^{-3}$ | $k_{\mathrm{N}(2 \mathrm{D})+\mathrm{C}_{6} \mathrm{H}_{6} / 10^{-11} \mathrm{~cm}^{3} \mathrm{~s}^{-1}}$ |
| :--- | :--- | :--- | :--- | :--- |

CCSD(T)/aug-cc-pVTZ + ZPE

Figure S6: PES for the reaction between $\left.\mathrm{N}^{2}{ }^{2} \mathrm{D}\right)$ and benzene, leading to the formation of $\mathrm{C}_{4} \mathrm{H}_{4} \mathrm{~N}+$ $\mathrm{C}_{2} \mathrm{H} 2(\mathrm{P} 7), \mathrm{C}_{4} \mathrm{H}_{4} \mathrm{NCCH}+\mathrm{H}(\mathrm{P} 8), \mathrm{C}_{6} \mathrm{H}_{5} \mathrm{~N}+\mathrm{H}(\mathrm{P} 15), \mathrm{C}_{6} \mathrm{H}_{5} \mathrm{~N}+\mathrm{H}(\mathrm{P} 16), \mathrm{C}_{6} \mathrm{H}_{5} \mathrm{~N}+\mathrm{H}$ (P17), $\mathrm{C}_{4} \mathrm{H}_{3} \mathrm{NCHCH}+\mathrm{H}$ (P18). Relative energies computed at CCSD(T)/aug-cc-pVTZ//B3LYP/aug-ccpVTZ level ${ }^{28-35}$ in $\mathrm{kJ} / \mathrm{mol}$. The red paths were not calculated in the work of Chin et al. ${ }^{36}$
