Computation details

Constant-potential method. To calculate the free energies of species involved in electrochemical reactions, we employed a constant-potential method (CPM) while accounting for solvent effects using the implicit solvation model provided by VASPsol. To illustrate the ΔG calculation using CPM, we use the Volmer reaction from HER as an example, where a proton from the solution adsorbs onto the catalyst surface, coupled with electron transfer from the electrode.

In the charge-neutral method (CNM), the Gibbs free energy change (ΔG) for the reaction $H^+(sol) + e^- \rightarrow H*$ is calculated as:

$$\Delta G_{cnm} = G(*H) - G(*) - G(H^+(sol)) - \mu_e \quad (1)$$

where $G(H*)$ and $G(*)$ are the free energies of the catalyst with and without hydrogen adsorption, respectively, $G(H^+(sol))$ is the free energy of the proton in solution at given pH; and μe is the electron energy, which is defined by the absolute electrode potential.

To make this calculation more computationally feasible, μ_e is referenced to the electron energy in the standard hydrogen electrode (SHE), denoted as μ_{SHE}, and the Nernst equation is applied. This reformulates the ΔG expression as:

$$\Delta G_{cnm} = G(*H) - G(*) - G(H_2)/2 + |e|U \quad (2)$$

When employing the constant-potential method, which accounts for the varying charge states of the catalyst during the reaction, the ΔG calculation is modified as:

$$\Delta G_{cpm} = G_{sol}(*H^{Q2}) - G_{sol}(*^{Q1}) - G(H_2)/2 + |e|U + (Q2 - Q1)\mu_e \quad (3)$$

where Q1 and Q2 represent the net charges on the catalyst before and after hydrogen adsorption, determined by the condition

$$E_F(*^{Q1}) = E_F(*H^{Q2}) = \mu_e \quad (4)$$

where E_F is the Fermi energy. The electron energy μ_e is calculated as:

$$\mu_e = \mu_{SHE} - |e| \cdot U_{SHE} \quad (5)$$

where U_{SHE} is the applied potential versus SHE, benchmarked to be −4.6 eV in VASPsol.[1]

The relationship between U_{RHE} and U_{SHE} is given by:

$$U_{RHE} = (\Phi - \Phi_{SHE})/e + 0.0592 \times pH \quad (6)$$

where Φ is the work function, determined by the energy difference between the vacuum level and the Fermi level. This relationship enables the calculation of the potential U by adding extra electrons. This approach allows us to model the potential-dependent free energy as a quadratic function $G(U)$, facilitating the analysis of reaction energy changes with varying potential.

To represent the constant-potential conditions, extra electrons are systematically added or removed to control the surface charge state. In evaluating the reaction barriers, the potential is calculated as the average of the potentials at the initial (U_{IS}) and final states (U_{FS}):

$$U_r = (U_{IS} + U_{FS}) / 2$$

This ensures the calculated free energy at constant potential accurately reflects the reaction environment, as outlined in earlier studies.[2, 3]

Slow-growth approach. In the thermodynamic integration (TI) method, the reaction free energy and kinetic barrier are obtained by applying a holonomic constraint on the reaction coordinate (ζ) during MD simulations and integrating over the average unbiased force associated with the reaction coordinate,[4, 5] The free energy difference between two reaction coordinates (ζ_a and ζ_b) is given by:

$$\Delta A(\zeta_a, \zeta_b) = -\int_{\zeta_a}^{\zeta_b} F(\zeta)d\zeta \quad (7)$$

Where $\Delta A(\zeta_a, \zeta_b)$ is the free energy difference between two reaction coordinates ζ_a and ζ_b and $F(\zeta)$ is the averaged constrained force along the reaction coordinate.

For the formation of H_2 in the second step of the HER ($*H + H_3O + e^- \rightarrow * + H_2 + H_2O$), the CV is defined as:

$$CV = \zeta(r) = |r_{Au(surface)} - r_{HA}| + |r_{Au(staple)} - r_{HA}| - |r_{HA} - r_{HB}| \quad (8)$$

where r_{HA} refers to the coordinate of the H atom adsorbed at the Au bridge site, and r_{HB} refers to the coordinate of the H atom on the hydronium ion (H_3O^+).

For the formation of *CO under alkaline conditions (*COOH $\rightarrow$ *CO + OH⁻), the

CV is defined as:

$$CV = \zeta(r) = |r_C - r_O| \quad (9)$$

where r_C refers to the coordinate of the C atom on the *COOH, and r_O refers to the coordinate of the O on the -OH group of *COOH.

H$_2$ formation: $CV = d1 + d2 - d3$

CO* and OH$^-$ formation: $CV = d1$
