Computational Details

The particle swarm optimization (PSO) method, integrated within the evolutionary algorithm and implemented in the Crystal structure AnaLYsis by Particle Swarm Optimization (CALYPSO) code,1, 2 was employed to identify the lowest-energy structures of $B_v C_x$ (x = 3-12, y = 1; x = 3, 5, 7, 9, 11, y = 2). Specifically, the number of layers was set to 1, the layer thickness was set to 0.2 Å, and a vacuum layer of 20 Å along the c-axis was introduced to prevent interlayer interactions, which were consistent with previously reported values.^{3, 4} Initially, random structures with specific symmetry were generated, where atomic coordinates were produced through crystallographic symmetry operations. Subsequent local optimizations were performed using the VASP code,^{5, 6} under a version with a fixed *c*-axis, employing the conjugate gradients method and terminating when the total energy changes fell below 1×10^{-5} eV per cell. Following the processing of the initial generation structures, 60% of those with lower enthalpies were selected to generate the subsequent generation structures via PSO. Additionally, 40% of the structures in the new generation were randomly created. Structural searches were carried out for 1-4 formula units, with a maximum of 30 atoms. Each generation consisted of 40 structures, and the calculations were iterated over at least 20 generations.

The scanning potential energy surface was constructed by calculating the energy of a single K atom at various positions above the B–C monolayer. A Python script⁷ was employed to automatically generate these positions, using the relaxed CONTCAR file of the optimal adsorption site within a 2×2 supercell as the input to determine the ideal adsorption height. For the BC₆ and BC₈ monolayers, 12 positions were generated in both the *x* and *y* directions, resulting in a total of 144 positions. Additionally, for the BC₁₁ monolayer, 12 positions were generated in the *x* direction and 8 in the *y* direction, totaling 96 positions. Relaxation for each position was performed using VASP code.^{5, 6} Given that most sites are not conducive to K atom adsorption, the K atom was constrained to move only vertically to achieve adsorption equilibrium. Upon completing the calculations, the Python script extracted the data and plotted the potential energy surface by calculating the energy differences between each site and the optimal adsorption site.

Supplementary Figures

Fig. S1 The planar average potential as a function of the distance along the *c*-axis for five B–C monolayers. Only the B–C layer (located at 10 Å) exhibits an obvious planar average potential, while the vacuum layer is flat, which indicates that there is no interlayer interaction between adjacent layers.

Fig. S2 (a)-(b) Crystal structures and (c)-(d) phonon spectra of BC_7 and BC_9 monolayers, respectively. The structures also include the electron local function (ELF). (e) represents their Young's modulus, and (f) represents their Poisson's ratio.

Fig. S3 AIMD simulations for (a) BC_6 , (b) BC_7 , (c) BC_8 , (d) BC_9 , and (e) BC_{11} monolayers at 300 K. The inset gives top and side view of the structure after 10 ps.

Fig. S4 AIMD simulations for (a) BC_6 , (b) BC_7 , (c) BC_8 , (d) BC_9 , and (e) BC_{11} monolayers at 600 K. The inset gives top and side view of the structure after 6 ps. Total energy remains equilibrium and the structures are not fractured or collapsed, indicating that they are thermal stable.

Fig. S5 Projected band structures of (a) BC_7 and (b) BC_9 monolayers. The metallic property is mainly contributed by the p_z orbitals, hence here only the p_z orbitals of C (yellow) and B (blue) are given.

Fig. S6 Charge density in the plane 1.6 Å above the sheet for (a) BC_7 , (b) BC_8 , (c) BC_9 , and (d) BC_{11} , respectively.

Fig. S7 Ion migration paths on the (a) BC_8 and (c) BC_9 and (e) BC_{11} monolayers. Green, red, and blue indicate different paths. The corresponding CI-NEB migration barriers of Li, Na, and K across three paths are depicted in (b), (d), and (f). The blue path has the lowest barrier, with Li, Na, and K ion migration energy barriers of 0.33, 0.12, and 0.06 eV for BC_8 , 0.37, 0.14, and 0.08 eV for BC_9 and 0.36, 0.14, and 0.07 eV for BC_{11} , respectively.

Fig. S8 (a) The migration pathways of K ions and (b) their corresponding CI-NEB migration barriers for the three pathways in BC₇. The Path 1 (in blue) represents the minimum K-ion migration path with migration energy barrier of 0.07 eV. It is noted that the BC₇ most stable adsorption site is on the center of B_2C_4 ring, and the optimal migration path is also along the center of B_2C_4 rings.

Fig. S9 ELF snapshots of K loaded on (a) K_4BC_6 , (b) K_5BC_7 , (c) K_7BC_9 , and (d) K_8BC_{11} , respectively. There is significant localization of the electrons between the K ions, which act as anionic electrons to minimize the repulsion between the K ions, thereby increasing the theoretical capacity.

Fig. S10 OCV as a function of K concentration in (a) BC_6 , (b) BC_7 , (c) BC_9 , and (d) BC_{11} , respectively.

Fig. S11 AIMD simulations of K_4BC_6 , K_5BC_7 , K_7BC_8 , K_7BC_9 , and K_8BC_{11} at 300 K. The inset gives top and side view of the structure after 5 ps.
